Abstract
Due to the technological development, remote sensing instruments and methods have become widespread in all segments of life (from precision agriculture through architecture to medicine). Among the innovative development of remote sensing instruments the 3D laser scanner is of outstanding importance. Horticulture applicability of terrestrial laser scanning technique is a new innovation in the precision agriculture. The structure of trees and branches, the canopy extension, the fruit yield, which can help to recognize some biophysical parameters can be determined. The examination was carried out with Leica ScanStation C10 terrestrial laser scanner in Karcag Research Institute of the Research Institutes and Study farm of the Centre for Agricultural and Applied Economic Sciences of the University of Debrecen. In this article the measuring principle, the parameters of the terrestrial laser scanner. Furthermore we have modelled the trees to could get to know the canopy structure and leaf area better are presented.

Keywords: laser scanning, LIDAR, 3D modeling of individual trees

INTRODUCTION

The production of marketable horticulture products is difficult without quality horticulture practice, which in many cases is primary condition of appropriate management system. The precision agriculture and precision horticulture contribute to the high quality yield production. Besides the environmental and field protection, the costs reductions, increases of efficiency are justified the widespread of precision techniques. Presently, the development of fast information technology gives our hand such methods like global positioning system (GPS), Geographic Information System (GIS), remote sensing (RS). Covered and uncovered ground can be quickly, accurately and cost effectively examined on large area (Burai, P. 2007). This ternary technology apace develop an integrated complementary in geospatial sciences and researches.

Remote sensing (RS) is rapidly developing discipline. Remote sensing, also called earth observation, refers to obtaining information about objects or areas at the Earth’s surface without being in direct physical contact with the object or area (Belényesi, M. et al. 2008). According to
Lóki, J. (1996) the remote sensing means not only a special data collection, but processing and evaluation of these data also. Remote sensing provides to get information from large areas beside/instead of traditional sampling data (Burai, P. 2007).

The principle of remote sensing based on interactions and investigations of electromagnetic radiation with material (e.g. earth’s surface). These thoughts were formulated in the early 1930s by Krinov Soviet scientist. The basis of remote sensing is incoming radiation to the object (E_ι). When the radiation incident upon the object’s surface, is either reflected (E_R) by the surface, transmitted (E_T) into the surface or absorbed (E_A) and emitted by the surface. These variables are depending by the wavelength (λ). So, it could be created the following equation:

\[ E_R(\lambda) + E_A(\lambda) + E_T(\lambda) = E_ι(\lambda) \]

It could be determined from the equation that on given wavelength the reflection, absorption and transmission are equal to the total incoming radiation. The values are always depended on the physical characteristics of the object and the geometric structure (Molenaar M. 1993). When a remote sensing instrument has a line-of-sight with an object that is reflecting solar energy, then the instrument collects that reflected energy and records the observation. Most remote sensing systems are designed to collect reflected (E_R) radiation (Short N. M. 2011). Based on the measured values it could be concluded to physical and possibly chemical characteristic of the observed object (Molenaar M. 1993).

There are two types of remote sensing: passive remote sensing and active remote sensing. Passive remote sensing is detected natural radiation that is reflected by the object or surrounding area being observed. Reflected sunlight is the most common source of radiation measured by passive sensors (Belényesi, M. et al. 2008). The active sensors emit a certain radiation. It could be measured the reflected part of this emitted energy from the object. Active remote sensing systems are available in all weather conditions, day or night. The principle of active remote sensing is already used in World War II. for RADAR (RAdio Detection And Ranging) detection. Radar works by sending out radio signals in microwave range, and then waiting for them to bounce off the ground and return. The reflected radar signals are sensed by the detector. By measuring the amount of time it takes for the signals to return. Another type of remote sensing technique is laser scanning (LIDAR – LIght Detection And Ranging). The LIDAR are similar to RADAR systems, but in this case a laser light sweeps the object or the earth’s surface (Belényesi, M. et al. 2008). The laser scanner analyzes a real-world or object environment to collect data on its shape and possibly

278
its appearance (e.g. color). The collected data can then be used to construct
digital, two-dimensional drawings or three-dimensional models useful for a
wide variety of applications. The advantage of laser scanning is the fact that
it can record huge numbers of points with high accuracy in a relatively short
period of time (Lerma García J. L. et al. 2008). The 3D model building is
occurred, if it is known the distances (so positions) of the measured points
to the laser scanner. Determination of one point’s distance could be
occurred based on 3 methods:

1. The mathematical basis of the triangle (trigonometry), which is at the
basis of these triangulation based measurement techniques. A
triangulation laser scanner uses the same principle to probe the
environment. It shines a laser pattern onto the subject and exploits a
camera to look for the location of the laser’s projection on the object.
The laser emitter and the camera are setup under a constant angle,
creating a triangle between them and the laser projection on the object,
hence the name triangulation. Because of this configuration, the laser
projection changes in the camera’s field of view depending on the
distance to the camera. This method is applied in short range and high
precision laser scanners.

2. The light waves travel with a finite and constant velocity in a certain
medium. Therefore, when the time delay created by light travelling
from a source to a reflective target surface and back to the source
(round trip) can be measured, the distance to that surface can be
evaluated. The measurement of these laser scanners are based on time-
of-flight (TOF) method

3. The emitted (incoherent) light is modulated in amplitude and fired onto
a surface. The scattered reflection is collected and a circuit measures the
phase difference between the sent and received waveforms, hence a
time delay. Typical phase-based scanners modulate their signal using
sinusoidal modulation, amplitude based (AM) or frequency based (FM)
modulation, pseudo-noise or polarization modulation (Lerma García J.

To be able to measure multiple points from the same scanner point of
view, the laser beam needs to be deflected. Instead of moving the laser
itself, a deflection unit is used (1. figure). Most deflection units make use of
a mirror because they are much lighter and can thus be rotated much faster
and with greater accuracy. A number of methods exist to deflect the laser
beam towards a specific direction without having to move the scanner itself
(Lerma García J. L. et al. 2008).
To the 3D modeling of a certain surface is necessary more scan stations sweep the object, so it could be get a point cloud, which is contain more million points. The instrument is put the scan stations in a common coordinate system, so it is create the spatial location of the target.

Airborne laser scanning has already been adopted and accepted as a very valuable tool in forestry applications shortly after its advent as a commercially available measurement technique in the 1990s. The using of terrestrial laser scanner (and mainly airborne laser scanning technology) has been even less spread in horticulture applications (Vosselman G. and Hans-Gerd M. 2010). Both in two areas (forestry and horticultural applications) with laser scanner technology it could be recognized the structure of trees, the canopy extension and else structural aspects, so it could be long term shadowing many biophysical processes and monitored the changes (Rosell J. R. et al, 2009). A number of studies have also focused on full reconstruction of tree elements, including tree stems for cross-section analysis (Pfeifer N. and Winterhalder D. 2004), tree branches (Gorte B. and Winterhalder D. 2004), leaf surface (Leaf Area Index – LAI) (Moskal L. M. et al, 2009; Antonarakis A. S. et al, 2010; Huang P. and Pretzsch H. 2010). These researches could help to recognize photosynthesis, growth, CO₂-sequestration and evapotranspiration (Li F. et al, 2002; Pereira A. et al, 2006; Rosell J. R. et al, 2009).

MATERIALS AND METHODS

On 1st March 2010 2 pear (Bosc kobak and William’s) and 1 apple varieties (Regal Prince) were planted in 3 replications into 9 lysimeters with compensation system of the lysimeter station of the Karcag Research Institute of the Research Institutes and Study farm of the Centre for Agricultural and Applied Economic Sciences of the University of Debrecen. Each lysimeter has a surface area of 0.8 m² and depth of 2 m. The
permanently maintained groundwater level is at the depth of 90 cm serving as the water supply (subsurface irrigation) of the trees in dry periods.

On 3rd September 2011 the investigated trees was scanned by Leica ScanStation C10 laser scanner. The instrument uses the time-of-flight (TOF) principle for ranging. A short laser pulse is emitted towards the object and is reflected on its surface; a part of the reflected radiation comes back to the scanner where it is detected by a sensor. The fast determination of objects is provided by a high scan rate of up to 50,000 points/sec. The emitted laser beam is 532 nm wavelength, so the color is green. The green laser light sweeps the objects; the deflection of laser beam is occurred by a Smart X-Mirror™ automatically spins polygon mirror system. Thus the scanner creates with high speed a point cloud. The maximum range of laser scanner is 300 m; it is depend on the albedo. The coherence of laser beam is high, but if increase the range – increase the beam divergence too – so the scanning error is more and more bigger. Because of the larger beam diameter is more probability that the laser beam hits an edge on the object, so the beam is split in two parts. The result of this mixed edge problem is inaccuracy of distance. This error is bigger in case of vegetation scanning, because the plants have less plain parts, like e.g. buildings. The beam divergence is 0.1 mrad; it means that the diameter of laser point is 10 mm on 100 m. This value is – in case of maximal measurement distance (on 300 m) – only 3 cm.

Fig. 2 Digital image mosaic of the seventh scan station
The Field-of-View (horizontal 360° and vertical 270°) of laser scanner is arisen from the construction of instrument, since the laser scanner doesn’t survey under itself in 90°. Near the laser emitter it could be found an auto-adjusting, high-resolution digital camera with zoom video. The integrated 4 megapixel (1920x1920 pixel) camera takes photos to color the point cloud. The Field-of-View of the camera is 17°, so the automatically spatially rectified (panoramic) dome was made form 260 images (fig. 2).

We have surveyed the full lysimeter station from 7 scan positions. The overlapping of scanning areas is provided the unifying of point cloud, and increased the accuracy of measurement. The scan resolution was 5 mm on 10 m; it means that on the right side the accuracy was below 1 cm.

The processing of raw point cloud was carried out by Cyclone 7.1 software which is developed from Leica, 3DReshaper software from TECHNODIGIT and the Geomagic Studio 10. The three softwares are appropriated to clean the point cloud form noises, and ideal for several engineering calculations.

RESULTS AND DISCUSSION

The laser scanning was carried out in Karcag Research Institute of the Research Institutes and Study farm of the Centre for Agricultural and Applied Economic Sciences of the University of Debrecen. After cleaning of point cloud a tree was chosen from the first lysimeter. The software could be fitted an object depending on the topology of the scanned point clouds. We have modelled the stem and the branches of investigated tree, and Cyclone fitted the best shape which was a cylinder (fig. 3). In software environment of 3DReshaper, Geomagic Studio and Cyclone also, we made a mesh to the point cloud. A mesh is a series of triangles that represents a surface.

Fig. 3 The cylinder model from branches in Leica Cyclone (a) and 3D meshes of first tree in lysimeter in Geomagic 10 (b) and 3DReshaper (c) software environment
The softwares generate meshes by using the points in a point cloud. For each adjacent trio of points in a cloud, a triangle is created. This has the effect of creating a visually coherent surface from the point cloud, and it is the primary method for modeling topography.

First, we have visually compared the mesh models. It could be determined that the Geomagic and 3DReshaper created a better mesh, than Leica Cyclone software. The help of proper mesh it could be recognised some characteristics of the investigated tree, such as (stem) diameter, height, surface and volume calculation too.

CONCLUSIONS

The laser scanning technology provides such a database, which can determine some characteristics of investigated trees with fast, non-destructive method. In the future we would like to recognize the length and angles of branches, the full 3D structure and the growing mechanisms of trees. These parameters could help in some precision horticulture applications. The geometry of trees and the canopy structure influence the incoming among of sun to the center of trees. Thus, optimal canopy and crown structure contribute to more yield. Further studies are also necessary to estimate the leaf area with laser scanning technology, since the dynamic of transpiration can be determined. The first step is developed and compared some modeling methods. Using this measurements water use efficiency of trees can be estimated. Based on the results, it could be possible to develop a water and energy saving irrigation system. This system can also be supplied by other remote sensing (e.g. hyperspectral) images could be given assistance (Nagy A. et al. 2009).

ACKNOWLEDGMENTS

The laser scanning was provided by the University of West-Hungary, Faculty of Geoinformatics. The authors thank Attila Váradi from Leica Geosystems Hungary Ltd. for his assistance in Leica software processing. This study is funded by TECH_08-A3/2-2008-0373 and TECH_08-A4/2-2008-0138 projects.
